Chapter 3: Alley Cropping

In this chapter:
- Defining Alley Cropping
- General Benefits and Limitations
- Alley Cropping Functions
- Design Considerations
- Tree Arrangement
- Tree and Shrub Selection
- Selection of Companion Crops
- Specialty and Biomass Crops
- Operation and Maintenance
- Economic Incentives for Alley Cropping
- Summary
- Success Stories
- Additional Resources

Alley Cropping

Alley cropping is broadly defined as the planting of two or more sets of single or multiple rows of trees or shrubs at wide spacings, creating alleys within which agricultural, horticultural, or forage crops are cultivated. The trees or shrubs may include valuable hardwood species, such as nut trees, or trees desirable for wood products. Shrub can provide nuts, fruit, or other products. This approach is sometimes called intercropping and multi-cropping (or silvoarable in Europe). Currently most of the emphasis and research focuses on pecan, chestnut, and eastern black walnut alley cropping applications. However, there are numerous other potential tree, shrub and crop combinations.

Role on the Farm

Alley cropping provides the opportunity to grow wood or other tree products such as nuts or fruit, while providing an annual income through the production of companion crops while at the same time realizing natural resource conservation.

Benefits of Alley Cropping

- Diversify farm enterprise
- Reduce erosion
- Improve water quality
- Protect crops
- Enhance wildlife
- Improve aesthetics

Diversifying farm products and supplementing income:

Alley cropping diversifies farm enterprises by providing short-term cash flow from annual crops while also providing medium- to long-term products from woody components. Timber and non-timber products may contribute to income generation from the farm. In addition to the potential for producing nuts, berries, and fruits, well-managed timber can provide a long-term investment.

Reducing soil erosion from wind and water:

Soils with a high erodibility index (>8) are highly susceptible to damage and are difficult to protect when used as crop land. The soil erodibility index provides a numerical expression of the potential for a soil to erode considering the physical and chemical properties of the soil and the climatic conditions where it is located. The higher the index, the...
greater the investment needed to maintain the sustainability of the soil resource base if intensively cropped.

Alley cropping protects fragile soils through a network of roots produced by the trees and supplemental ground-cover resulting from fallen leaves and the companion crop. Rows of trees, shrubs, and/or grasses planted on the contour of a slope will also serve to reduce soil movement down the slope.

**Reducing erosion on sloping cropland:**
The interception of rainfall by the tree canopy and increased infiltration due to tree and herbaceous roots protects the soil; water quality is improved due to interception of sediment by herbaceous cover in tree rows and interception, sequestration, and decomposition of agricultural chemicals by tree and herbaceous root environment. Agricultural chemicals (e.g., nitrogen) leached beyond the root zone of the agronomic crops can be absorbed by the deeper root systems of the tree, hence minimizing the leaching of chemicals into the ground water resulting in improved water quality.

**Microclimate impacts:**
Trees and shrubs improve crop production by slowing wind speed and reducing wind erosion, modifying the crop microclimate with similar effects to that of windbreaks (see Chapter 6 on windbreaks). Alley cropping can reduce crop evapotranspiration by 15-30 percent and increase water content in the tillage layer by 5-15 percent. Deep tree roots transport soil nutrients to leaves. Leaves contribute organic matter to soil and release nutrients as they decompose.

**Protecting crops:**
Alley cropping reduces damage from insect pests by reducing crop visibility, diluting pest hosts due to plant diversity, interfering with pest movement, and creating habitat more favorable to beneficial insects.

**Enhancing wildlife habitat and aesthetics:**
Linear plantings of trees and/or shrubs in an agricultural landscape increases the habitat diversity for wildlife, both through increased amount of edge and/or as a result of the increased diversity (vertical and horizontal) of vegetation. Increased vertical complexity has been correlated with increased bird numbers. These areas can also serve as protective corridors for wildlife movement and provide a food source.

**Limitations to Alley Cropping:**
Alley cropping, as with other forms of multi-cropping, requires more intensive technical management skill and marketing knowledge. The following limitations should be considered:
- Requires a more intensive management system including specialized equipment for the tree management and additional managerial skills and training to manage multiple crops on a given site
- Removes land from annual crop production and may not provide a financial return from the trees for several years
- Requires a marketing infrastructure for forest products that may not be presently established
- Trees may be an obstacle to crop cultivation if not carefully planned and managed
- Trees compete with companion crops for sun, moisture and nutrients
- Companion crops may compete with trees for moisture and nutrients
- Herbicide drift from crops may damage trees

**Alley Cropping Functions**
There are numerous mechanisms in which alley cropping impacts the landscapes to which it is applied, including water management, nutrient cycling, soil quality, microclimate modification and pest management.
- Alley cropping impacts water management by altering the hydrologic cycle through increased water infiltration via disruption of overland flow by the tree/grass strip. Water cycled through the system is more thoroughly filtered and any excess is gradually released.
• Nutrient cycling and soil quality are impacted as deeply rooted trees exploit lower soil horizons and cycle the nutrients to the surface through litterfall. Additional nitrogen is added to the nutrient pool if a nitrogen-fixing tree or shrub is used. Reduced soil erosion by wind and water help maintain soil quality. Additional moisture is added to the site through interception of rainfall by the tree canopy.
• Microclimates are modified due to reductions in wind velocity which reduces air temperatures and evapotranspiration of intercropped plants and soil.
• Pest management can be strengthened through the structural diversity in the landscape developed by the intentional association of trees and crops. Alley cropping creates habitat to build up biodiversity and associated populations of natural enemies of insects, diseases, or weed pests and can interrupt pest cycles.
• Similar to the function of riparian forest buffers, alley cropping practices may help intercept, fix and biodegrade sediments, nutrients, pesticides, and other biological pollutants present on the site.
• Similar to the establishment of windbreaks, alley cropping may improve wildlife habitat by providing food, cover, nesting sites, and travel lanes for a variety of wildlife species.
• Incorporation of trees and shrubs add opportunity for additional products which are derived from the tree/shrub component (wood, nuts, fruit, foliage) as well as the option to plant sensitive crops which can be grown due to the protection from the trees.

Not all of these functions may exist with each application of alley cropping. The function is dependent upon the way the plant components are manipulated in the design process. There is also a lack of understanding of all the different interactions that can occur with the different combinations of tree/shrub/herbaceous (annual and perennial) plants. For a given design, we do not have enough information to evaluate all the different pest interactions to definitively state that beneficial insects will be favored and negative pests will be reduced, although there are examples of this.

Designs Unique to Each Landowner
Each alley cropping practice can be uniquely designed to reflect landowner needs and site potential. However, there are physical interactions between the rows of woody species and the companion crop that should be understood and reflected in plans for the alley cropping practice design.

Physical growth traits of individual trees and how these influence the crop, are based on three factors:
A. Light Competition
B. Root Competition for Water and Nutrients
C. Allelopathy

A) Light Competition (aboveground)
A tree species should be selected that best accommodates the sunlight requirements of a specific crop. Some tree species have small leaves and feathery foliage casting a light shade and lend themselves well to alley cropping. When considering a tree species for an alley cropping practice, small leaves and light shade is preferable to heavy shade.

In what ways can light competition be reduced?
• Spacing
When the distance between rows of trees/shrubs is increased, the years an alleyway may be cropped with minimal competition from the trees is also increased.
• Row Orientation
An East-West orientation of tree rows will maximize the sunlight received by an alley crop, provided the topography permits this arrangement. Trees may have to be planted on the contour if erosion is a consideration. Trees may be planted in other orientations if prevailing winds have a negative influence on crop yields.
• Maximizing available light
Trees with small fine leaves will allow more
light through the canopy. These leaves decompose rapidly and allow nutrients to be recycled into the soil faster. As decomposed materials contribute organic matter to the soil, the soil moisture-holding capacity is increased. Increased organic matter enhances soil microbe and earthworm activity. This also improves soil tilth and health.

- **Understanding crown and foliage characteristics - phenology**
  Utilize trees that leaf-out late in the spring and/or drop leaves early in the fall. If the agronomic crop component matures in the early spring, such as winter wheat (Triticum aestivum L.), a tree that breaks dormancy late is ideal; alternatively, a crop that is harvested late in the fall is appropriate with a tree that drops its leaves early. Black walnut (Juglans nigra) is a good example of a tree that satisfies both scenarios.

- **Timely Thinning and Pruning**
  Properly thinning trees within rows can maintain semi-open crown conditions. Maintained through regular thinning, these openings can help continue the vigorous growth of shade intolerant companion crops. Pruning basal branches before they reach 1” in diameter improves future wood quality and thins the depth of the canopy permitting more sunlight to reach companion crops.

**B) Root Competition (below ground)**

Competition for water and nutrients between the tree and the intercropped species not only affects the yields of the companion crop but also the growth of the trees.

**What ways can root competition be reduced?**

- **Understanding rooting zones**
  Vertical distribution of root systems varies among species. Deep-rooted species have a reduced volume of roots near the surface (good for minimizing competition with adjacent crops). Erosion can be addressed through ground cover establishment and management.

- **Which trees have deep roots?**
  Tree species have different site requirements. For instance, as a rule, wetland species tend to be shallow rooted. While a potential species list has been included in the appendices, it is always useful to consult your local forester for assistance in determining species suitable to your planting site.

- **What can be done if the trees are more shallow rooted?**
  Through the use of a Ripper, Coulter, or Chisel Plow, roots can be severed (the addition of subsurface knives may also be used to sever more roots outside the rip). Trenching trials strongly suggest that even during the early years of tree development, competition for water and/or nutrients is the major reason for reduced crop yields. With early (beginning with young trees) and repeated (annually or biennially) ripping lateral roots, the number of tree roots can be significantly decreased in the plow zone. The remaining roots will remain active deeper in the soil profile.

**C) Allelopathy (Chemical Interactions)**

Traditionally, the term allelopathy denotes the negative biochemical influence exerted by one plant on the growth of nearby plants. For example, pine needles may produce acids that inhibit growth of plants on the forest floor, while roots of black walnut trees produce a compound called juglone, which also inhibits the growth of other plants.

A broader definition would also include positive influences. For example, some plants (e.g., legumes, European black alder, black locust) fix nitrogen that can benefit nearby plants.

Chemical interactions can be controlled by choosing plant combinations that work together. Juglone, for instance, does not affect all plants. Conversely, nitrogen-fixing plants are only useful to neighboring plants that require extra nitrogen.
**Tree arrangement**
The tree and/or shrub row(s) are placed at intervals across the crop field, depending on the purpose, either on the contour or perhaps even perpendicular to prevailing troublesome winds. Several factors are used to determine the interval between the row(s) of trees or shrubs including slope length, field width, crop light requirements and equipment width.

As mentioned earlier, landowner objectives will determine the products to be harvested from the alley cropping practice. These objectives also determine the arrangement of trees/ shrubs and crops and the set of management practices needed to obtain those products. Alley cropping practices are highly diverse and range from simple to complex. Plantings can consist of a single tree species or a number of species. Similarly, single tree rows or multiple rows may be used.

There are several key factors to consider when planning and establishing the practice on a given site:

**Layout: Tree Arrangement**
- Single or mixed species
- Number of tree rows - single vs. multiple
- Alley width: Between row spacing
- Within row spacing

With a conservation perspective in mind, slope length relates to the spacing needed to reduce water erosion. The light requirement for the crop or forage to be grown in the alleyway must be considered prior to tree establishment. Finally, alley width must be set as multiples of the widest field equipment width.

**Single vs. Mixed Species** - The row(s) of trees can have either a single species in the row or mixed species. A single species is the easiest to plant but a mixed species planting with similar growth rates and site requirements may provide greater economic and environmental diversity.

Factors to consider when deciding how many rows to establish and the arrangement of the trees within the rows may be based on a number of potential benefits including:

- **Annual crop being produced and area removed from production by tree/shrub rows**
- **Desired tree/shrub crops and management needed to enhance production (such as weed control and pruning)**
- **Erosion concerns that multiple rows and combinations of trees/shrubs/grasses can better address**
- **Wildlife habitat created through multiple rows of combined trees/shrubs/grasses**

**Single vs. Multiple Row Sets of Trees** - Single rows take up the least amount of space but the trees will probably require pruning to enhance the quality of the future wood product. Multiple rows, however, will result in self pruning of the interior row(s). Conifers are a good choice as the “trainer” trees in the outside rows since hardwood species will tend to bend toward the light in the alleyway thus reducing their wood value except as chips. Nitrogen-fixing “nurse trees” can also be used.
Top: Triple row of trees using conifers to train high-value hardwoods. A single-row tree strip is also shown. Bottom: aerial view of single, double and triple row configurations for alley cropping at the Horticulture and Agroforestry Research Center, New Franklin, Mo.

Advantages to single rows:

- Environment maintained
- Less tree to tree competition
- Reduced competition between components
- Wildlife habitat enhanced
- Plant-insect relationships increased
- Economics improved

Single rows create the proper environment for nut trees to develop full crowns. Trees in single rows which are spaced further apart develop wider, more branched crowns. Conversely, if high value tree form is important, then closely spaced trees may encourage self pruning and straight bole development. In single rows, trees are open on at least two sides, and therefore have less competition between trees within each row, when compared to multiple row configurations. Single tree rows add diversity to a typical row crop field. Researchers think the greatest value to wildlife of woody herbaceous buffers are the benefits created through breaking up the traditional monoculture setting associated with agriculture. Vegetation change and structural diversity is an important tool in controlling agricultural pests. Products coming from the farm are diversified through the addition of trees and their products.

Advantages to double rows:

- Environment maintained
- Reduced competition
- Wildlife habitat
- Economics

When rows are offset, double rows of trees maintain similar advantages to that of single row plantings while improving the potential to realize environmental benefits, such as soil and water protection. Compared to rectangular grid patterns of tree planting, double rows allow maximum utilization of space for companion crops.

Competition for light between trees can be reduced through offset row configurations.* Multiple rows of trees planted in offset configurations maintain exposure of a majority of each trees crown/canopy to sunlight. Double rows provide the same benefits as a single row alley crop setting, but allow structure (vertical and horizontal vegetative layering and density components) and diversity (variety of species planted) to be increased. This creates an environment for greater utilization of the tree row by increased numbers of wildlife species. Finally, products coming from the farm are further diversified.
It is also possible that thinned trees can provide early economic gain (prior to final crop tree maturation).

[*As mentioned, caution should be observed since deciduous hardwood trees will exhibit a tendency to grow towards light. If an environment of unequal lighting is created (more light to one side of a trees’ crown), most hardwood species will grow towards sunlight, and away from competition. This can cause devaluing of the tree for wood products due to sweep (stem curvature).]

Advantages to multiple rows:

- Benefit from competition between tree rows
- Wildlife habitat
- Plant-Insect relationships
- Economics

Certain trees will benefit from some light competition. For high value wood, it is desirable to grow a single, straight stem. Trees and/or shrubs planted on either side of a high value tree species, can be used to train the stem of that tree. By using ‘trainer’ trees on either side of the high value tree, natural pruning and straight stem growth can be encouraged. Ultimately, this starts the process (may also require pruning) of producing a straight, clear (small or no knots) log of higher quality than might be grown in an open setting. However, choosing the correct ‘trainer’ species is important because you do not want the outside trees to outgrow your center tree. If they do, they will provide too much shade.

Wildlife habitat potential increases greatly with a wider row of trees. Increased numbers of animals will use this area for travel lanes and the interior creates protective cover opportunities for birds and small mammals.

Plant-insect benefits are the same for single and double row configurations, though some additional advantages may be realized by diversifying the species planted.

Economic benefits are similar to double row configurations. As with double rows, additional trees per acre in multiple row configurations may also qualify these plantings for cost-share assistance and create opportunities for medium-term tree crops to be removed for cash flow (e.g., trees grown for landscaping).

Crown competition between adjacent trees (A) as compared to the increased growing space available to individual trees when planting in an offset configuration (B). Double or triple rows of long-needled hard pines (e.g., cold tolerant loblolly or pitch x loblolly hybrids) can be grown either as (A) or (B). A byproduct of a double or triple planting is the potential for pine straw production within tree rows.

Tree and shrub arrangement

To enhance the growth of trees in multiple-row plantings, staggering the trees between adjacent rows will permit maximum crown development. Staggered spacing provides more room to grow.

Alley Width: between tree row/set spacing: If wood production is of primary importance, closer row spacing is desirable. Wider row spacing is preferred when nut production is desired.
Equipment Travel Lanes: The use of trees planted in rows can allow equipment passage in any number of directions.

The spacing should also be adjusted based on multiples of the widest farm equipment to be used in the alley way. Spacing to accommodate equipment is particularly important in nut production when early crown development is desirable. Plan alleys such that full, or multiple, passes of the equipment are utilized. For example, if using a 13-foot wide disk it may be desirable to have an alleyway 60 feet wide. This allows for 4 passes with the disk (52 feet) and a buffer (to ensure damage is not done to the base of the tree) of 4 feet adjacent to each tree row (8 feet; 4 feet on either side of the cropped alley).

The number of years that light-demanding crops are to be grown in the alleyways is another consideration:

- 60 feet spacing will generally allow crop production (e.g. corn, soybeans, cereals, etc.) for 5-10 years
- 80-120 foot spacing will allow production for up to 20 years or more
- As the shade increases over the life of the trees, it may be necessary to change the companion crop being grown in the alleyway (see plant material section).

Within Tree Row Spacing: The primary objective for the trees, and the cost of the planting stock, will help determine the within row spacing. If erosion control is desired, a closer spacing would give better results. If the tree stock is of unknown origin and quality, a closer spacing would also be desirable to give more opportunities to select the best quality trees during succeeding thinnings. Closer spacing may also be required if minimum numbers of trees per acre are required to meet government cost share requirements. However, if expensive grafted tree stock is used for nut production, a wider spacing may be used to reduce cost.

For example, trees that are grown tightly spaced will have a tendency to grow up, towards the light. This growth trait is highly desirable when growing trees for quality wood production. Additionally, as these tightly spaced trees begin to shade one another, each of their branches in the shade will begin to die and eventually fall off. This is called self-pruning, and is again desirable when trying to grow high quality wood in timber production.

Tree and Shrub Selection: Desirable Characteristics

There are a number of desirable characteristics for trees or shrubs that will be grown in an alley cropping system. It is not necessary (probably not possible) that all of the following characteristics be exhibited by one tree species:

- Produces a commercially valuable product or multiple products (i.e., timber, nuts) that has an acceptable local market.
- Is relatively fast growing (medium growth rate on high value trees is acceptable) or highly valued for production or conservation benefits
- Produces appropriate shade for the companion crop
- Is adapted to a variety of sites and soils
- Is deep-rooted with minimal roots at the soil surface to minimize competition with crops in the alleyway.
• Has foliage with minimal acid-generating potential if companion crops prefer a pH neutral soil. Conifers acidify soil, combine well with acid loving crops.
• Does not produce growth inhibitory chemicals (allelochemicals) that would prevent some crops from growing near them (e.g., black walnut)
• Has a growing season that complements the companion crop
• Produces wildlife benefits

Selecting companion crops
Companion crops are planted in the alleys between the tree rows. The choice of companion crop will vary depending on the types of trees selected and the crop(s) desired by the grower. There are three major groups of crops which can be grown in an alley cropping practice: 1) Row/cereal and forage crops; 2) Fruits and other specialty crops; and 3) biomass producing crops.

Initially, the growing environment in the alley will be favorable to row crops requiring full sun (corn, soybeans, wheat) or forages. Potential companion crops include row/cereal crops, forages, fruits and other specialty crops, biomass producing crops.

As trees grow taller and develop larger crowns, they will exert greater influence on the growing environment in the alley with increased shade, water and nutrient competition and humidity levels, along with decreased temperatures and decreased wind movement.

While availability of sunlight is a primary factor that determines how well row crops or forages perform in the alley, water and nutrient competition is even more significant. The tree canopy density will be partially determined by the spacing of the trees within a row and the width between tree rows. This spacing will also influence below ground competition.

<table>
<thead>
<tr>
<th>Plant Materials: Trees for Alley Cropping</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Black walnut</strong>: Outstanding markets available for wood. Opportunities exist for the sale of wild nuts, cultivars provide a higher return. Produces light shade, has a short foliage period, and is deep rooted. The juglone allelochemical limits companion crop choices somewhat (esp. avoid nightshade plants).</td>
</tr>
<tr>
<td><strong>Pecan</strong>: Markets available for both wood and nuts. Markets exist for nuts from native wild pecans and for cultivars. Nuts more valuable than the wood. More shade produced than with walnut but no allelochemicals.</td>
</tr>
<tr>
<td><strong>Oaks</strong>: The wood has a high value and the acorns are good wildlife food. The oaks are relatively slow growing and produce fairly dense shade.</td>
</tr>
<tr>
<td><strong>Chestnuts</strong>: Chinese chestnut produce valuable nuts at an early age, are blight resistant and adapted to the climate of the eastern U.S. Prices are high and markets are growing for domestic producers.</td>
</tr>
<tr>
<td><strong>Nut or fruit bearing shrubs</strong>: Hazelnuts, pawpaws, blueberries, etc. could be used as stand-alone hedgerows or in combination with other taller tree species.</td>
</tr>
</tbody>
</table>

Tree/shrub selection for row crops
Corn, soybeans, wheat, milo, barley, oats, potatoes, pumpkins, lettuce, peas, etc. have demonstrated success in alley cropping. Most of these crops have high light demands. Using corn in the first few years speeds tree growth by creating a greenhouse effect for the tree rows. In an alleyway 60 feet wide, shade will limit their use after 5-10 years depending on the tree species.
Selection of forage crops – In an alley cropping practice, forage crops such as fescue, orchard grass, bluegrass, or alfalfa, are grown for hay production between rows of planted trees, but are not grazed. This distinguishes the alley cropping practice from a silvopasture practice.

Kentucky 31 tall fescue and orchard grass tolerate considerable shade and are very productive cool-season grasses. Other potential forages that show shade tolerance include Kentucky bluegrass, ryegrass, smooth brome, timothy and white clover. Winter annuals such as cereal grains, crimson clover, and hairy vetch must be reseeded every year and only provide one cutting of hay, but do not compete with the trees and provide good erosion control.

Cool vs. warm-season forages
It is also necessary to consider whether a cool or warm season crop and/or forage may be more appropriate for the site conditions and objectives. Studies conducted by the University of Missouri have found that many cool-season legumes and grasses produce greater biomass when grown under partial shade as compared to full sun. Some warm-season grasses showed similar responses, but most were southern temperate zone species.

Advantages and Disadvantages of Cool Season Forages
Cool-season perennial species are most productive in the spring when temperatures are typically cool and moisture plentiful. They grow less or become dormant during the hot summer months when moisture is often limiting, then increase growth in the fall.

Cool-season forages can be highly competitive with tree crops for moisture and nutrients, especially in the spring as trees break dormancy. As young trees are becoming established, it is desirable that no vegetation grow within a 3-foot radius. To maximize the growth of older trees, vegetation should be controlled in a diameter approximately equal to the crown diameter size. However, this may or may not result in the greatest economic gain.

Advantages and Disadvantages of Warm-Season Forages
The root systems associated with warm-season forages are typically deeper than cool-season grasses. This makes them an excellent choice for controlling erosion and protecting sub-surface water from leached pesticides and nutrients. These forages will likely be less competitive in the early spring when many trees are beginning their annual growth. Warm season “clump” grasses provide excellent habitat for quail in combination with woody shrubs.
Warm-season forages grow vigorously in the hot summer months. Therefore, a consideration is that this may put them in competition with trees and other woody vegetation at a time of the year when water is quite possibly the most limited resource. On the other hand, if a tree species puts on its growth in late spring, in certain instances a warm-season forage can make a good companion crop.

The point is that compatibility, even seasonal compatibility, must be considered when selecting trees, shrubs, grasses, and crops for an alley cropping practice.

**Integrating Specialty Crops into an Alley Cropping Practice**

Most often associated with the forest farming practice, specialty crops also have potential for integration into alley cropping practices. Landscaping plants, Christmas trees, small fruit trees or shrubs and berries can be grown either temporarily between the permanent in-row crop trees or in the alleyways. As the alleyways become more shaded, shade tolerant species such as redbud, dogwood and spruce could be grown for landscaping if there is a nearby market. Plants which can be marketed for their medicinal, ornamental, or food values (including St. John’s Wort, wildflowers for seed, pumpkins, etc.) also provide unique opportunities for alley cropping. Species that are light demanding can be established in the alleyways while those requiring some shade can be planted within the tree rows as shade develops.

**Specialty crops that can be produced in full sun include:**
- Horticultural plants, such as tomatoes, pumpkins and blackberries
- Forages, grains and oilseeds
- Tree crops, such as nuts
- Seeds, such as wildflower or select grasses
- Christmas trees
- Shrubs and other landscaping plants
- Trees for lumber and wood fiber products

**Biomass Crops**

Both woody and herbaceous plants for biomass production could be an option for the alley-
ways. “Soft” hardwood species such as cottonwood, hybrid poplars, willow, sycamore and silver maple could be grown for pulp, paper or oriented strand board if markets are available. Herbaceous biomass crops (e.g. switchgrass) are another alternative.

**Operation and Maintenance**

**Pest management:** Periodic inspection of the crops and trees is recommended to detect and identify possible pests. Insects and diseases can be significant factors in reducing the health and vigor of both the tree crop and the intercrop. The corrective actions should minimize the impacts on beneficial insects.

**Fertilization and nutrient management:** A normal fertility program should be applied for the intercrop in the alleyway. Generally, fertilization of the tree crop is not needed, but fertilizing the intercrop may also benefit the trees. Competition for nutrients can be minimized by root pruning or by adding more nutrients. Nutrients can be added in the form of chemical fertilizer, animal manure or a wide range of other materials. This may also include the use of living mulches or green manures.

**Canopy management (Pruning):** If there is too much shade under an existing stand of trees, the canopy can be pruned to allow more light to reach the understory plants. You may be able to accomplish this by clear-stem pruning for improved timber production. This involves the removal of branches low on the stem of a tree in order to raise the height at which the canopy begins. This allows more light to enter the understory from side angles while also creating adequate space for operating equipment. Remember, removing more than 40% of the trees foliage will significantly reduce the growth of the tree. It is best to always have 40-50% of a tree’s height in crown or foliage.

**Alley cropping example:** Paulownia and winter wheat in China. Through careful pruning, the proper shade canopy can be developed and light levels can be manipulated in an alley cropping practice. Often, the alley cropping practice will transition to more shade tolerant crops, or extensive tree removal by thinning will be needed in order to maintain light levels.

**Periodic root “training” will improve crop yields:** Based on research into tree and crop interactions it has been shown that even during the early years of tree development, competition for water and/or nutrients is the major reason for reduced crop yields. By early (beginning with young trees) and repeated (annual, biennial) deep ripping of lateral roots, the number of tree roots can be significantly decreased in the plow zone. Row crops will continue to produce commercial yields even as shade levels increase.

**Weed Control:** Weed control for an alley cropping includes both the rows of trees and the intercrop. For the tree row(s), weeds need to be minimized usually for the first three to five years in a band about three feet on each side of the trees. Weed removal can be done in a number of different ways, from herbicides and cutting, to cultivation and mulching. An additional consideration for use in controlling weeds adjacent to trees may include fabric barriers or living mulches. Nothing will improve the growth of trees and shrubs like the control of competing grasses.
Maintenance tasks specific to trees:

- **Replanting:** Replant all trees or shrubs that have failed for the first 3 years.
- **Branch Pruning:** Pruning of the trees may be necessary to improve wood quality, the microenvironment for the companion crop, allow equipment access, or correct storm damage.
- **Root Pruning:** Deep ripping of tree roots (up to 24 inches deep) projecting into the companion crop area will reduce competition. Unless down from the outset, do not rip both sides of the trees the same year. Allow a 2-year interval before ripping the other side. Deep ripping will need to be repeated on an annual or biennial interval.
- **Thinning:** The tree rows will normally need to be thinned to increase light in the alleyways and speed production of high value crop trees.

To achieve the objective of maximum tree growth rates throughout the timber rotation, growers must be willing to periodically thin trees. Failure to do so dramatically and adversely impacts future tree growth rates and rotation length.

**Economic Incentives for Alley Cropping**

There are many agencies offering programs that can be used to establish and maintain agroforestry practices on private land. One of the most significant of these is the USDA Natural Resource Conservation Service (NRCS) Environmental Quality Incentive Program (EQIP) that may be used to support startup costs of establishing an alley cropping practice.

The EQIP program is designated to address environmental concerns associated with agricultural production. Landowners engaged in livestock or agricultural production can apply for 1 to 10-year contracts through a competitive application process based on environmental benefits. Eligible lands include cropland, rangeland, pasture, forestland, and other farm and ranch lands. Conservation practices are designed with the help of USDA/NRCS and other agencies to address the locally-identified priority resource concerns. EQIP contracts provide cost-share payments up to 50 percent of the establishment cost for conservation practices and various incentive payments. For alley cropping practices, EQIP

will pay $50 per acre for first 3 years on land planted in trees and the grass strip adjacent to trees. No more than 50% of the cropland can be enrolled.

NRCS Standard 311 identifies the guidelines for establishing an alley cropping practice for EQIP. For more information, contact your local USDA/NRCS office.

Additional USDA programs to establish and maintain an alley cropping practice are offered through the Forest Service (FS) and the Sustainable Agriculture Research and Education (SARE) program. See chart below for a list of incentives offered by these federal agencies or consult the UMCA publication “Funding Incentives for Agroforestry in Missouri.”

### Funding incentive for Alley Cropping through EQIP:
$50 payment per acre for first 3 years on land in trees and grass strip adjacent to trees. No more than 50% of the cropland can be enrolled.

### Cost Share Opportunities:
Alley cropping is the tree or shrub component of an overall conservation management system for cropland or hayland. To be an effective conservation management system, several other conservation practices need to be considered for inclusion in the system depending on the objectives to be achieved. (Numbers in parentheses are NRCS Conservation Practice Codes.)

- Conservation Crop Rotation (328)
- Crop Residue Management (329, 344)
- Contour Farming (330)
- Contour Buffer Strips (332)
- Contour Orchard & Other Fruit Area (331)
- Filter Strip (393)
- Forage Harvest Management (511)
- Grassed Waterway (412)
- Stripcropping, Contour (585)
- Terrace (600)
- Pasture and Hayland Planting (512)
- Pest Management (595)
- Wildlife Upland Habitat Management (645)

**Note:** Cost share reimbursement rates vary by state and by year.

### Summary
Alley Cropping needs to be part of an overall management system including crop rotation, crop residue management, combinations of buffer practices, pest management and nutrient management. Alley Cropping can help diversify farm enterprises, protect soil, improve air and water quality, enhance fish and wildlife habitat, conserve biodiversity, and beautify the landscape.

### Success Story
**Paul Smith**
20-acre alley cropping practice, Northwest MO, near Claremont

“I guess I was a little hesitant at first to plant trees. I wondered at times what some of my farmer friends and neighbors would think of covering good bottomland with trees. My wife reminded me that her father had spent his lifetime clearing this off and now we’re planting it back in trees. In 1999 we seeded this field to orchard grass, and alfalfa. The first cutting that year produced about 3 tons per acre, and I feel that we benefit from the alley cropping because we have a short-term benefit of the crops between the tree rows -- and eventually, my family or someone else will benefit from the tree crop.”
Success Story
Dan Shepherd
Shepherd Farms – Bluegrass hay and pecan alley cropping practice, buffalo ranch and agritourism business, Clifton Hill, Mo.

Dan Shepherd raises buffalo for processing into lean, high-quality meats and jerky, in addition to his pecan and bluegrass hay alley cropping practice. Shepherd Farms is also a nationwide leader in production, wholesale and retail distribution of Eastern Gamagrass seed.

“Alley cropping is ideal for achieving both our production and conservation benefits,” said Shepherd. “We earn an annual income off the ground, while the trees are being established. We also enjoy an abundance of wildlife in the habitat created by alley cropping. While the crops are growing we see deer, turkey and quail utilizing this ground and the trees.”

Success Story
Bill & Sue Ellen Stouffer
Cedar Hill Farms Chestnuts in Napton, MO

Bill and Sue Ellen planted the first 250 chestnut trees on Cedar Hill Farms in the spring of 2009. Additional trees have been added since, now totaling 20 acres of chestnuts, and an additional acreage of elderberries. The Stouffers worked closely with the Center for Agroforestry in establishing these trees, combining multiple varieties of Castanea mollissima (Chinese chestnuts) with winter wheat, pumpkins, and hay harvested between rows as the trees grew to maturity.

Winter wheat harvest in a young Chinese chestnut orchard.

Association for Temperate Agroforestry, Alley Cropping:
http://www.aftaweb.org/about/what-is-agroforestry/allely-cropping.html
1. What factors affect the width between your rows?

2. What are some of the advantages and disadvantages to alley cropping?

3. What are advantages and drawbacks of utilizing narrow vs. wide alleyways?

4. Identify two management practices that are critical to maintaining tree growth over time.

5. Why is root pruning performed on tree/shrub species in alley cropping?

6. Removing what percent or more of the tree’s foliage can have a serious impact on the growth of the tree?

7. How do you determine how far apart to plant trees in a tree line and how far apart to plant the tree rows? Is there such a thing as a wrong distance, such as too far apart or too close together?
1. What factors affect the width between your rows? Landowner goals and objectives, desired crops, uses for trees, and width of existing crop production equipment all impact between and within row widths.

2. What are some of the advantages and disadvantages to alley cropping? Advantages: Short-term cash flow, trees benefit from crop fertilization, sun crops compete with weeds, reduce runoff, form of windbreaks, and provide increased economic diversity and long-term payoff. Disadvantages: Tree rows are obstacles for cultivation, provide competition for sunlight, moisture, and nutrients, and require more intensive management. Herbicide drift from crops may damage trees. Sun crops will need to be exchanged for more shade tolerant crops over time.

3. What are advantages and drawbacks of utilizing narrow vs. wide alleyways? Narrow alleys with more tree rows permit greater production of trees and shrubs per acre of land putting an emphasis on the value of the woody crop. Narrower alleys will also become shaded within just a few years forcing a shift from sun to shade loving crops. Wide alleys permit sun loving crops to be grown for many years and are often more compatible with farm equipment.

4. Identify two management practices that are critical to maintaining tree growth over time. Ongoing weed control around the base of the trees, using herbicides, mulch, fabric barriers or living mulches is absolutely essential for rapid tree growth and establishment. As the trees age and grow, thinning out crowded trees within the row will enable the trees to maintain maximum growth rates over the long haul.

5. Why is root pruning performed on tree/shrub species in alley cropping? Tree roots can be pruned (severed) or “trained” to reduce competition for water and nutrients.

6. Removing what percent or more of the tree’s foliage can have a serious impact on the growth of the tree? Removing over 40% of the crown of the tree will reduce its growth.

7. How do you determine how far apart to plant trees in a tree line and how far apart to plant the tree rows? Is there such a thing as a wrong distance, such as too far apart or too close together? (See question #1) Depending on the emphasis of nut or wood production, and what kinds of crops are planned on, the width of the alleys must be adjusted to meet these plans. Wood production is compatible with narrow rows and multiple rows; nut production requires single rows and wide spacing between trees.

A “wrong” distance would be any planting configuration that does not meet the landowner’s short-, medium- and long-term objectives resulting in lower production from desired crops or reduced tree growth or poor tree form. Row-to-row distance also must match with existing equipment.
